Recommenders

Ryan Henning

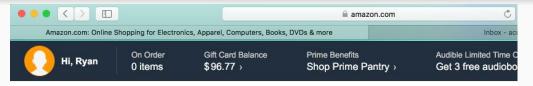

(heavily based on Dan Becker's slides and on Giovanna's notes)

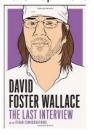

- Where are recommenders used? (Hint: everywhere!)
- What does our dataset look like?
- What are the high-level approaches to building a recommender?
 - Content-based
 - Collaborative filtering
 - Matrix factorization
- How do we evaluate our recommender system?
- How to deal with "cold start"?
- What are the computational performance concerns?

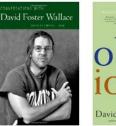

Where are recommenders used?

We combed our catalog and found courses and Specializations that we think match your interests. Browse our recommendations below, and start learning something new today.

PANDORA

Free personalized radio that plays the music you love

Business Goals:

What will the user like?

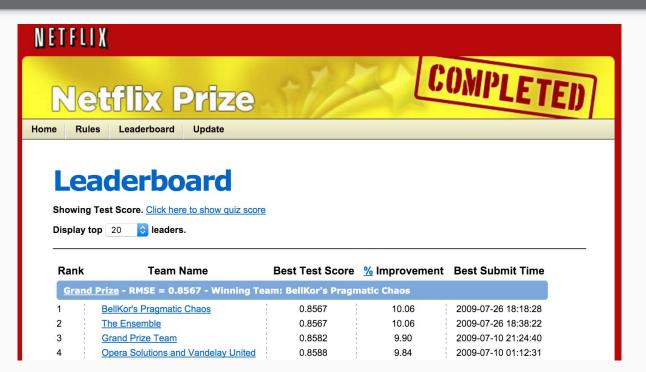

What will the user buy?

What will the user click?

Name a business that cares are each of these, and tell us why they care.

galvanıze

Data Science Canon: Netflix's \$1,000,000 Prize (Oct. 2006 - July 2009)

Goal: Beat Netflix's own recommender by 10%.

Took almost 3 years.

The winning team used gradient boosted decision trees over the predictions of **500** other models.

Netflix never deployed the winning algorithm.

Let's learn recommenders.

Today we'll learn:

- 1. How to **build** a recommender,
- 2. How to evaluate your recommender, and
- 3. How to **deploy** your recommender.

... and tomorrow we'll do a <u>case study</u> with recommender systems.

What are the high-level approaches to building a recommender?

Popularity:

- Make the same recommendation to every user, based only on the popularity of an item.
- E.g. Twitter "Moments"

Content-based (aka, Content filtering):

- Predictions are made based on the properties/characteristics of an item.
- User behavior is not considered.
- E.g. Pandora Radio

Collaborative filtering:

- Only consider past user behavior.
 (not content properties...)
- User-User similarity: ...
- Item-Item similarity: ...
- E.g.
 - o Netflix & Amazon Recommendations,
 - o Google Ads,
 - Facebook Ads, Search, Friends Rec.,
 News feed, Trending news, Rank
 Notifications, Rank Comments

Matrix Factorization Methods:

Find latent features (aka, factors)

			Ite	m		
		A	В	С	D	
	Al	1	?	2	?	
	Bob	?	2	3	4	
User	Cat	3	?	1	5	
	Dan	?	2	?	?	
	Ed	2	?	?	1	

We have <u>explicit</u> ratings, plus a bunch of missing values.

What company might have data like this?

Btw, we call this the *utility matrix*.

		Item				
		A	В	С	D	
	Al	0	1	0	1	
	Bob	0	0	1	0	
User	Cat	0	1	1	1	
	Dan	1	0	0	1	
	Ed	0	1	0	0	

We have <u>implicit feedback</u>, and no missing values.

What company might have data like this?

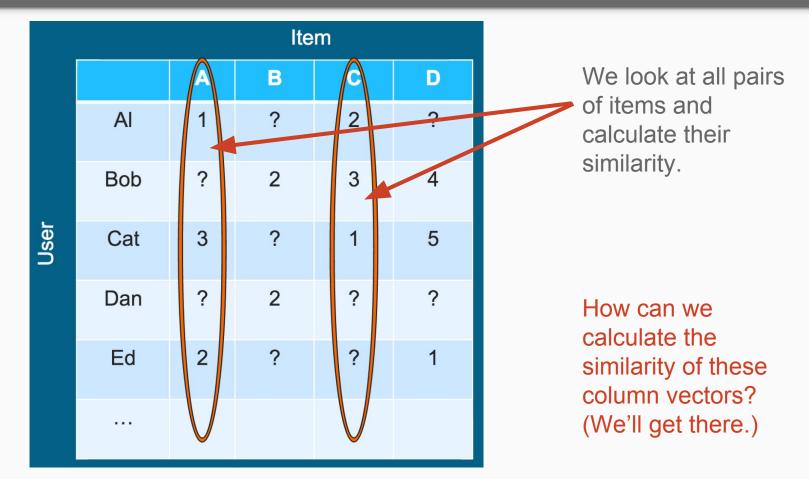

We look at all pairs of users and calculate their similarity.

How can we calculate the similarity of these row vectors? (We'll get there.)

User-User:

			Ite	m		
		A	В	С	D	
•	Al	1	?	2	?	
	Bob	?	2	3	4	
User	Cat	3	?	1	5	

Let:

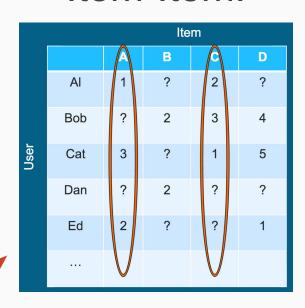

m = #users,

n = #items

We want to compute the similarity of all pairs.

What is the algorithmic fefficiency of each approach?

Item-Item:

User-User: O(m²n)

Item-Item: O(mn²)

Similarity Metric using Euclidean Distance

What's the range?
$$\operatorname{dist}(a,b) = ||a-b|| = \sqrt{\sum_i (a_i-b_i)^2}$$

But we're interested in a similarity, so let's do this instead:

What's the range? $similarity(a,b) = \frac{1}{1 + dist(a,b)}$

When use this?

galvanize

Similarity Metric using Pearson Correlation

What's the range?
$$\frac{\text{cov}(a,b)}{\text{std}(a)*\text{std}(b)} = \frac{\sum_i (a_i - \bar{a})(b_i - \bar{b})}{\sqrt{\sum_i (a_i - \bar{a})^2} \sqrt{\sum_i (b_i - \bar{b})^2}}$$

But we're interested in a **similarity**, so let's do this instead:

When use this?

What's the range?

similarity(a, b) = 0.5 + 0.5 * pearson(a, b)

galvanıze

Similarity Metric using Cosine Similarity

What's the
$$\cos(\theta_{a,b}) = \frac{a\cdot b}{||a||||b||} = \frac{\sum_i a_i b_i}{\sqrt{\sum_i a_i^2} \sqrt{\sum_i b_i^2}}$$
 range?

But we're interested in a **standardized similarity**, so let's do this instead:

When use this?

Similarity $(a,b) = 0.5 + 0.5 * \cos(\theta_{a,b})$ what's the range?

Similarity Metric using Jaccard Index

What's the range?
$$similarity(a,b) = \frac{|U_a \cap U_b|}{|U_a \cup U_b|}$$

 U_k denotes the set of users who rated item k

The Similarity Matrix

Pick a similarity metric, create the similarity matrix:

	item 1	item 2	item 3	
item 1	1	0.3	0.2	
item 2	0.3	1	0.7	
item 3	0.2	0.7	1	

Say user *u* hasn't rated item *i*. We want to predict the rating that this user *would* give this item.

$$\operatorname{rating}(u, i) = \frac{\sum_{j \in I_u} \operatorname{similarity}(i, j) * r_{u, j}}{\sum_{j \in I_u} \operatorname{similarity}(i, j)}$$

 $I_u = \text{ set of items rated by user } u$ $r_{u,j} = \text{ user } u$'s rating of item j

We order by descending predicted rating for a single user, and recommend the top *k* items to the user.

This calculation of predicted ratings can be very costly. To mitigate this issue, we will only consider the *n* most similar items to an item when calculating the prediction.

$$\operatorname{rating}(u, i) = \frac{\sum_{j \in I_u \cap N_i} \operatorname{similarity}(i, j) * r_{u, j}}{\sum_{j \in I_u \cap N_i} \operatorname{similarity}(i, j)}$$

 $I_u = \text{set of items rated by user } u$ $r_{u,j} = \text{user } u$'s rating of item j N_i is the n items which are most similar to item i

Deploying the recommender

In the middle of the night:

- Compute similarities between all pairs of items.
- Compute the neighborhood of each item.

At request time:

Predict scores for candidate items, and make a recommendation.

How do we evaluate our recommender system?

Is it possible to do cross-validation like normal?

Before we continue, let's review: Why do we perform cross-validation?

Quick warning: Recommenders are inherently hard to validate. There is a lot of discussion in academia (research papers) and industry (here, Kaggle, Netflix, etc) about this. There is no ONE answer for all dataset.

For this slide, the question marks denote the holdout set (**not** missing values).

We can calculate MSE between the targets and our predictions over the holdout set.

(K-fold cross-validation is optional.)

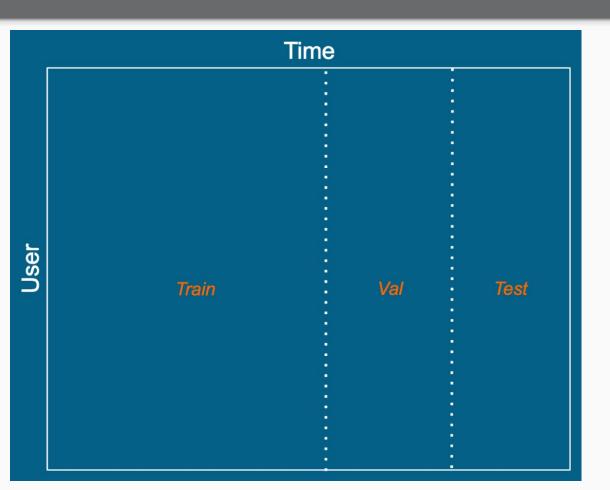

Recall: Why do we perform cross-validation?

Why isn't the method above a true estimate of a recommender's performance in the field?

Why would A/B testing be better?

Alternate way to validate:

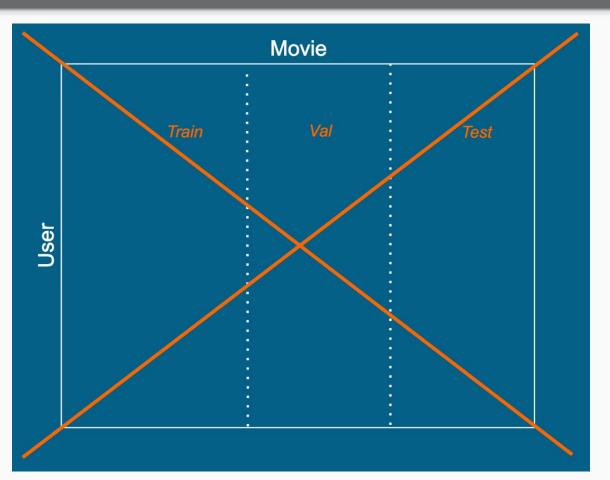

What's the deal with this?

I.e. Why might we prefer doing this instead of the more "normal" cross-validation from the previous slide?

How to deal with "cold start"?

Scenario: A new <u>user</u> signs up. What will our recommender do (assume we're using item-item similarities)?

One strategy: Force users to rate 5 items as part of the signup process. <u>AND/OR</u> Recommend popular items at first.

Scenario: A new <u>item</u> is introduced. What will our recommender do (assume we're using item-item similarities)?

One strategy: Put it in the "new releases" section until enough users rate it <u>AND/OR</u> use item metatdata if any exists.

How to deal with "cold start"?

Scenario: A new <u>user</u> signs up. What will our recommender do (assume we're Youtube and we're using item popularity to make recommendations)?

This really isn't a problem...

Scenario: A new item is introduced. What will our recommender do (assume we're Youtube and we're using item popularity to make recommendations)?

One strategy: Don't use <u>total</u> <u>number of views</u> as the popularity metric (we'd have a *rich-get-richer* situation). Use something else...

Matrix Factorization for Recommendation

Warning: There are a lot of acronyms in this lecture!

Ryan Henning

- UV Decomposition (UVD)
- SVD vs UVD
- UVD vs NMF
- UVD via Stochastic Gradient Descent (SGD)
- Matrix Factorization for Recommendation:
 - Basic system:
 - UVD + SGD... FTW
 - Intermediate topics:
 - regularization
 - accounting for biases

Least

Squares!

$$R_{m \times n} \approx U_{m \times k} V_{k \times n}$$
 $r_{ij} \approx u_{i:} \cdot v_{:j}$

- You choose k.
- *UV* approximates *R* by necessity if *k* is less than the rank of *R*.
- Usually choose: k << min(n,m)
- Compute *U* and *V* such that:

 $\arg\min_{U,V} \sum_{i,j} (r_{ij} - u_{i:} \cdot v_{:j})^2$

SVD vs UVD

SVD:

- $R = USV^T$
- *U* is an orthogonal matrix
- S is a diagonal matrix of decreasing positive "singular" values
- *V* is an orthogonal matrix
- Has a unique, exact solution

UVD:

- R ~= UV
- U and V will not (likely) be orthogonal
- Has many approximate, non-unique solutions:
 - non-convex optimization; has many local minima
- Has a tunable parameter k

UVD vs NMF

UVD:

- By convention: R ~= UV
- ... (see previous slides)

NMF is a specialization of **UVD**!

Both are approximate factorizations, and both optimize to reduce the RSS.

NMF:

- By convention: V ~= WH
- Same as UVD, but with one extra constraint:
 all values of V, W, and H must be non-negative!

UVD vs NMF (continued)

UVD and NMF are both solved using either:

- Alternating Least Squares (ALS)
- Stochastic Gradient Descent (SGD)

You did **ALS** yesterday, so let's do **SGD** today!

(and we'll see why SGD has some advantages for recommender systems)

UVD via Stochastic Gradient Descent (SGD)

Boardwork... (take notes!)

ALS vs SGD

ALS:

- Parallelizes very well
- Available in Spark/MLlib
- Only appropriate for matrices that don't have missing values (we'll call this a dense matrix in this lecture)

SGD:

- Faster (if on single machine)
- Requires tuning learning rate
- Anecdotal evidence of better results...
- Works with missing values
 (we'll call this a sparse matrix in this lecture)
 (we'll see how missing values are handled soon!)

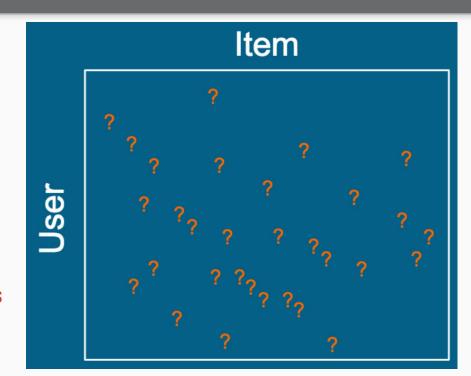

Matrix Factorization for Recommendation

Recall: An explicit-rating utility matrix is usually VERY sparse...

We've previously used SVD to find latent features (aka, factors)... Would SVD be good for this sparse utility matrix? (Hint: No!)

What's the problem with using SVD on this sparse utility matrix?

Would UVD (or NMF) work better than SVD to find latent factors when the utility matrix is sparse?

(Hint: Consider ways to change the SGD algorithm to handle missing values in the sparse utility matrix.)

SVD vs UVD (revisited)

SVD:

- $R = USV^T$
- ...
- Bad if R has missing values!
 - You are forced to fill in missing values.
 - Solution fits these fill-values (which is silly).
 - Makes for a much larger memory footprint.
 - Slow to compute for large matrices.

UVD:

- R ~= UV
- ...
- Handles missing values when computed via SGD.

$$\arg\min_{U,V} \sum_{i,j \in \mathcal{K}} (r_{ij} - u_{i:} \cdot v_{:j})^2$$
Set of indices of known rating

UVD (or NMF) + SGD... FTW!

UVD + SGD makes a lot of sense for recommender systems.

In fact, NMF + SGD is 'best in class' option for many recommender domains:

- No need to impute missing values.
- Use regularization to avoid overfitting.
- Optionally include biases terms to communicate prior knowledge.
- Can handle time-dynamics (e.g. change in user preference over time).
- Used by the winning entry in the Netflix challenge.

Warning: Don't forget to regularize!

Since now we're fitting a large parameter set to sparse data, you'll most certainly need to regularize!

$$\arg\min_{U,V} \sum_{i,j\in\mathcal{K}} (r_{ij} - u_{i:} \cdot v_{:j})^2 + \lambda(||u_{i:}||^2 + ||v_{:j}||^2)$$

Tune lambda: the amount of regularization

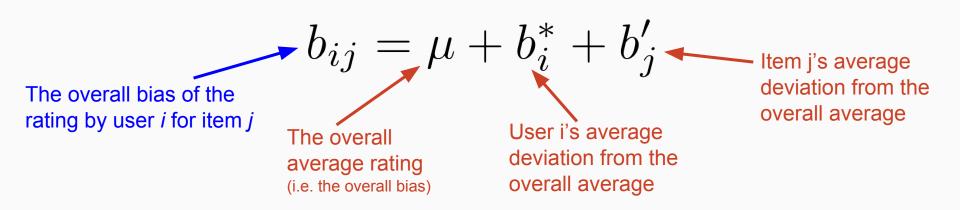

Accounting for Biases (let's capture our domain knowledge!)

In practice, much of the observed variation in rating values is due to item bias and user bias:

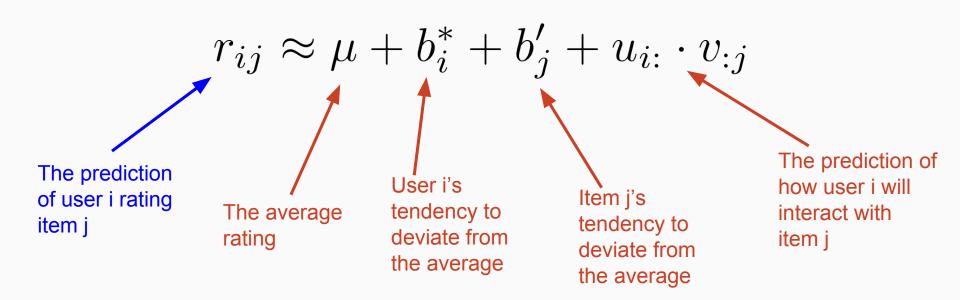

- Some items (e.g. movies) have a tendency to be rated high, some low.
- Some users have a tendency to rate high, some low.

We can capture this prior domain knowledge using a few bias terms:

We added bais terms... now: The 4 parts of a prediction

New part!

Ratings are now estimated as:

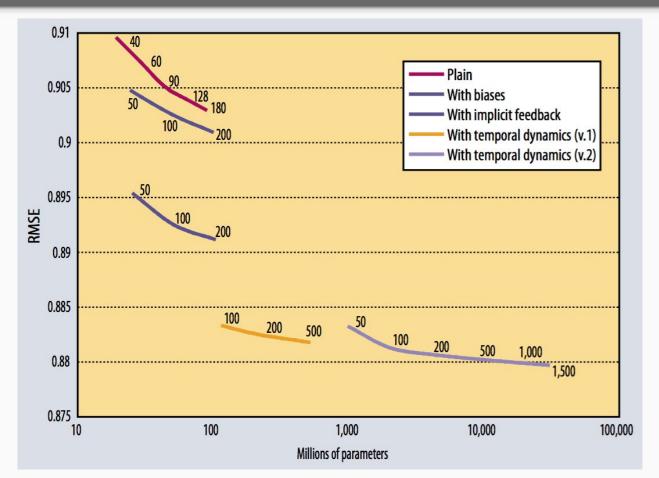

$$r_{ij} \approx \mu + b_i^* + b_j' + u_{i:} \cdot v_{:j}$$

The new cost function, with the biases included:

$$\arg\min_{U,V,b^*,b'} \sum_{i,j \in \mathcal{K}} (r_{ij} - \mu - b_i^* - b_j') - u_{i:} \cdot v_{:j})^2 + \lambda_1 (||u_{i:}||^2 + ||v_{:j}||^2) + \lambda_2 ((b_i^*)^2 + (b_j')^2)$$
New part!

From the paper: "Matrix Factorization Techniques for Recommender Systems"

Root mean square error over the Netflix dataset using various matrix factorization models.

Numbers on the chart denote each model's dimensionality (k).

The more refined models perform better (have lower error).

Netflix's inhouse model performs at RMSE=0.9514 on this dataset, so even the simple matrix factorization models are beating it!

Read the paper for details; it's a good read!
